KEYWORDS Endodontic cements, Bioceramics, Obturation techniques, Warm gutta-percha techniques, Cold gutta-percha techniques.

penetration and growth of microorganisms within it, as well as percolation of tissue fluids susceptible to degradation (1,2). To achieve a proper obturation of the root canal, two main factors are crucial: the root canal obturation technique and the endodontic cement. Several root canal obturation techniques are available, and those most commonly used can be divided into two groups.

1. Warm gutta-percha techniques, such as carrier-based obturation (3,4), continuous-wave compaction technique, plasticized technique, warm vertical compaction (5-9).
2. Cold techniques, namely lateral compaction, and single cone technique (10-13).

The purpose of the cement (14,15) is to facilitate the flow of the gutta-percha, to fill the spaces not filled by the gutta-percha itself, and to create an adhesive interface on the canal walls. However, the cement appears to be a locus minoris resistentiae for bacterial infiltration, since all types of cement currently available on the market are slightly resorbable, with the formation of empty spaces; consequently, they should be used in the smallest possible quantity.

Bioceramics are non-metallic, biocompatible, and inorganic materials that include zirconia and alumina, bioactive glass, coatings and composites, hydroxyapatite, and resorbable calcium phosphates (16). Today, new bioceramic cements can be used as substitutes of MTA or as root canal sealers (16).

BioRoot RCS (Septodont) has been reported to induce, *in vitro*, the production of osteogenic and angiogenic growth factors by human periodontal ligament cells (17). Moreover, it has lower cytotoxicity than other conventional root canal sealers, and it may induce hard tissue deposition (18,19). This material also has

INTRODUCTION

Root canal obturation aims to fill and seal, in all the three dimensions, the endodontic space, in order to prevent

antimicrobial activity (20). The powder contains tricalcium silicate, zirconium oxide, and povidone; the liquid is an aqueous solution of polycarboxylate and calcium chloride. Bioceramic cements are inductive materials, meaning that during hardening, when they come in contact with tissue fluids, calcium hydroxide reacts with phosphatase enzymes, thus inducing the formation of hydroxyapatite (21).

It was also demonstrated that these types of cement could be used as either root filling materials or root canal sealers in combination with gutta-percha for filling root canals. *In vivo* studies show excellent results, although Torabinejad emphasizes that the new bio-ceramic cements are indicated by recent clinical research as the future of root canal obturation, but they still need further investigation, as there is no long-term *in vivo* and *in vitro* studies in the literature (21).

There is not a standard method used to measure the bonding of a sealer to the root dentin; for this reason, the quality of the adhesion of the root filling material is commonly tested using bond strength tests and microleakage (22). Microleakage is described as the "spread of bacteria, oral fluids, ions, and molecules into the tooth and filling material interface" (23).

Apical leakage is regarded as the most common cause of endodontic failure and is influenced by several variables, such as different obturation techniques, chemical and physical properties of the root canal filling materials, and the presence or absence of the smear layer. This is referred to as primary failure or primary infiltration.

In a recent study (24) micro-CT scans were used to compare the 3D filling performance and the presence of radiographic translucencies of three different root canal filling techniques: warm vertical condensation, carrier-based technique, and single cone with bioceramic sealant; obturation volume, pore-volume, and pore rate were investigated. No obturation technique revealed completely filled root canal systems. The filling techniques employed in this study have similar features: they were biocompatible, radiopaque, and inert, providing a stable apical and intracanal seal.

Both continuous-wave and carrier-based techniques are built on the concept of minimum sealant interface, whereas the single-cone technique of bioceramic sealant originates from Grossman's concept of the maximum interface of the sealant with the gutta-percha cone intended as support (15).

Still, few studies are available concerning this category of cements, and most of them focus on the analysis of their excellent biological properties. For this reason, in this study, it was decided to focus on their behavior within the root canal when used in association with different obturation techniques.

The aim of this study was to evaluate the sealing ability of a bioceramic endodontic sealer (BioRoot RCS) and a ZOE sealer (Pulp Canal Sealer) at the apical thirds when used in combination with three different obturation techniques.

The null hypothesis tested was as follows.

1. The bioceramic endodontic cement can seal the apex similarly to traditional endodontic ZOE cement.
2. The bioceramic endodontic cement can similarly seal the apex when used in combination either with cold or warm obturation technique.

MATERIALS AND METHODS

Eighty intact human single-rooted maxillary premolars, recently extracted for orthodontic reasons, were included in the study. After the cleaning of remaining tissues, a $\times 4.5$ stereomicroscope (Nikon SMZ645; Nikon, Tokyo, Japan) was employed to rule out any external radicular cracks.

Samples were stored in 0.9% saline solution (SALF SPA, Cenate Sotto, Italy) at a temperature of 37°C to prevent dehydration. After preparing the access cavity, pre-curved stainless steel manual K-files # 8, and # 10 (Sweden & Martina, Due Carrare, Italy) were used to define the working length.

All chemo-mechanical procedures for preparation of the samples were performed by two calibrated operators (GM and VV).

NiTi Mtwo File (Sweden & Martina, Due Carrare, Italy) instruments were used for root canal shaping following the manufacturer's instructions with an endodontic motor (X-SMART TM Plus; Dentsply Maillefer, Ballaigues, Switzerland) set at 250rpm; 2.5 ml of 5% sodium hypochlorite (Nicol 5 dental; Ognalab, Muggiò, Italy) was used after each rotary instrument by syringe-needle irrigation with a 31-gauge needle tip. Sodium hypochlorite was preheated at 50°C. Apical patency was maintained by using a # 10 K-type file after each larger file. The final irrigation phase was carried out with 2 ml of 17% EDTA (Ognalab, Muggiò, Italy) for 2 minutes, followed by the final rinse of 5 ml of 5% NaOCl for 5 minutes, to optimize the removal of inorganic and organic components. After instrumentation, canals were dried with paper points.

Teeth were randomly divided into five groups and filled with different techniques and materials.

- Group 1 was filled using Thermafil® Obturators (Dentsply/Maillefer) with Pulp Canal Sealer™ (Kerr), n=20.
- Group 2 was filled using Thermafil® Obturators (Dentsply/Maillefer) with BioRoot™ RCS (Septodont) bioceramic sealer, n=20.
- Group 3 was filled using warm vertical condensation with traditional Pulp Canal Sealer™ (Kerr), n=20.
- Group 4 was filled using a Single GP cone with BioRoot™ RCS (Septodont) bioceramic sealer, n=20.
- Group 5 was filled with warm vertical condensation with BioRoot™ RCS bioceramic sealer (Septodont), n=20.

After root canal obturation, all dental surfaces were covered with nail varnish, except 2 mm around the area of the tooth apex which were left exposed. A solution

of ammoniacal silver nitrate (ammoniacal silver nitrate and distilled water 1:4) was prepared, and the diluted solution was filtered with a millipore filter (0.22- μ m filter, Carrigtwohill, County Cork, Ireland) mounted on a syringe. Under laboratory light, each tooth was placed in a test tube with diluted ammoniacal silver nitrate solution. After 24 h, specimens were thrice rinsed in water for 10 min. Nail varnish around the tooth was removed with acetone, and each tooth was placed in a test tube with a diluted solution of photo-developer (Kodak, Rochester, NY, USA) (ratio of 1:10 photo-developer:distilled water). After 8 hours, teeth were rinsed thrice in water for 10 min. Each tooth was embedded in transparent self-curing acrylic resin. The teeth were then sliced with a low-speed diamond saw under water cooling to prevent frictional heat (Isomet; Buehler, Lake Bluff, NY, USA) into two slices along their long axis and perpendicularly to the root. Samples were examined with a digital microscope. Two observers (DP, MF) independently scored the amount of tracer along the interface. The apical leakage was evaluated following the procedure described by Limkangwalmongkol et al. (25). In case of a score discrepancy, the sample was evaluated again by the two operators, and a common decision was taken. The Bonferroni and Anova tests were used to assess

sealer), which is 0.59 mm (Fig. 1). Group 2 (same sealer applied with Thermafil technique) reached an average of

FIG. 1 The average of apical leakage was found in Group 4.

FIG. 2 Group 2 reached an average of 0.665 mm leakage.

FIG. 4 The highest results belong to Group 1.

FIG. 5 The second highest results belong to Group 2.
